# THE RELATIONSHIP BETWEEN THE COLOR AND LUMINOSITY OF STARS NEAR THE SUN 

OLIN J. EGGEN<br>LICK OBSERVATORY, UNIVERSITY OF CALIFORNIA

The tabulation and description of all the individual stars was once considered to be the ultimate goal of astronomy. This Herculean task, which can no longer be seriously considered since the number of known stars and the variety of their physical and astrometric properties available for observations are so great, has been considerably lightened by the application of statistical methods.

The observed quantities that we shall deal with here are

| $V_{E}$ | The apparent, visual magnitude. |
| :--- | :--- |
| $(P-V)_{E}$ | The color or difference between the visual and the photographic |
| $\pi(t)$ | magnitude. <br> The trigonometric parallax. |

The values of $\pi(t)$ and $V_{E}$ are combined to give the absolute visual magnitude,

$$
\begin{equation*}
M_{V}=V_{E}+5+5 \log _{10} \pi(t) \tag{1}
\end{equation*}
$$

It is assumed that the nearby stars are not affected by interstellar absorption. The correlation to be investigated is that between $M_{V}$ and $(P-V)_{E}$ and will be referred to as the color-luminosity array.

The three samples of nearby stars to be discussed are characterized as follows, for $(P-V)_{E}<+1^{\mathrm{m}} 25$ :

| Group | $\pi(t)$ | Weight | $M_{V}$ | Number | Per cent <br> observed |
| :---: | :---: | :---: | :---: | :---: | :---: |
| I | $>0.050$ | $>36$ | All | 52 | 90 |
| II | $>0.050$ | $16-36$ | $<+4.55$ | 63 | 95 |
| III | $0.040-0.050$ | $>20$ | $<+4.55$ | 29 | 80 |

The objects in groups I, II, and III are listed in sections A, B, and C, respectively, of table I where they are numbered as in the Yale Parallax Catalogue [1]. The spectral types in the last column of table I, which are followed by a Roman numeral indicating the luminosity class, are from the Yerkes Spectral Atlas [2], or from other sources stated to be on the same system. The types preceded by the prefix " d " for dwarf, or " g ," for giant, were assigned at the Mount Wilson Observatory [3]; unpublished types, determined at the Lick Observatory by J. H. Moore, for a few southern stars are also included.

TABLE I
Parallax Stars Bluer Than $(P-V)_{E}=+1$ m 25

| Yale | Star | $V_{B}$ | $(P-V)_{B}$ | $\pi(t)$ | Wt. | $M_{V}$ | Sp. |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Since the distribution of energy in the M-type dwarfs is such as to cause the colorsystem used here to lose its resolution, stars of the spectral type later than K6, or with color greater than $+1^{\mathrm{m}} 25$, have been omitted and are discussed by G. E. Kron in another paper in this volume. Also, to prevent as much as possible the contamination of the observed colors by companion stars, all known visual binaries with a visual magnitude difference between the components of less than 3 m .5 have been eliminated. The sample of stars was chosen, and the mean parallaxes with their weights were taken, from the General Catalogue of Trigonometric Stellar Parallaxes [1]. Since the parallaxes attributed there to the Dearborn, Stockholm, Uppsala, and

London Observatories are few in number and carry low weight, they have been eliminated from the catalogue means. In the few cases where additional parallaxes, not included in this catalogue, have become available they have been incorporated into the means with the precepts stated in the catalogue. Only parallaxes determined at more than one observatory have been used.
Before discussing the sample of stars near the sun, we shall first establish a "standard" color-luminosity array from the observations of stars in two galactic

The main sequence of the Praesepe Cluster
clusters: Praesepe and the Pleiades. A plot of the Praesepe cluster stars with $(P-V)_{E}$ between $+0^{\mathrm{m}} 28$ and $+1^{\mathrm{m}} 25$ is shown in figure 1. For stars in a cluster, equation (1) reduced to $M_{V}=V_{E}+K$, where $K$ is a constant for all cluster members only if the size of the cluster is small in comparison with its distance from the sun. The Praesepe cluster is distant enough to insure a constancy in $K$ sufficient for our purposes, and at the same time it is close enough to permit accurate observation of the faintest cluster members. A value of $K=-6 m 04$ has been adopted and will be justified later. Various cluster members, which were selected by Klein Wassink [4] on the basis of their community of motion, have been observed at Lick [5], at McDonald by Johnson [6], and at Hamburg by Haffner and Heckmann [7]. The combined observations of color and magnitude are represented in figure 1, where stars that depart more than 0.15 from the thin line connecting the filled circles are marked as crosses. Since all but one of these latter stars fall above the main sequence, that is, they are apparently too bright, it is reasonable to assume that they are mostly undetected double stars.

Accurate determinations of the colors and magnitudes of stars in the Pleiades cluster are available only to $(P-V)_{E}=+0^{\mathrm{m}} 5$. The observations used here were made by Johnson and Morgan [8] at the McDonald Observatory, and the colors have been corrected by 0 m 03 for instellar reddening-a value determined by Johnson and Morgan from their additional observations of the ultraviolet magnitudes of the cluster stars. If it is assumed that the Pleiades and Praesepe stars, with colors between $+0^{\mathrm{m}} 28$ and +0 m .50 are identical, then a comparison of the magni-

tudes of the stars in the two clusters gives $K$ (Praesepe) $-K$ (Pleiades) $=-0{ }^{\mathrm{m}} 46$, or $K$ (Pleiades) $=-5^{\mathrm{m}} 58$. The color-luminosity array for the Pleiades stars is plotted in figure 2 where the two crosses indicate known binaries. The heavy line in the figure is taken from figure 1 . We shall assume that the hatched area, which contains most of the Pleiades stars with $M_{V}$ between 0 and $+3^{m}$, is a continuation of the main sequence.

To return to the nearby stars, most of their colors and apparent magnitudes have been determined photoelectrically by the author with the Lick Observatory 12-inch refractor, and with the 9 -inch refractor of the Commonwealth Observatory, Mount Stromlo, Australia. A few of the stars have also been observed by Johnson and Morgan [9], at the McDonald Observatory, and by observers at the Royal Observatory, Cape of Good Hope [10]. All of the magnitudes and colors have been reduced to a common system and, when more than one value is available, the mean has been used.

The sample of stars to be considered first is given in table IA. This group of stars with $(P-V)_{E}<1 \mathrm{~m} 25$ represents 90 per cent of all of those known, from trigono-
metric parallaxes with a weight greater than 36 , to be within 20 parsecs of the sun. Since a weight of 36 corresponds to a probable error of $\pm 0$ ". 005 in the parallax, and since from equation (1) we have

$$
\begin{equation*}
\Delta M_{V}=\Delta V_{E}+2.17 \Delta \pi(t) / \pi(t) \tag{2}
\end{equation*}
$$

then the probable errors of the values of $M_{V}$ in the table, arising from errors in the parallaxes, are all less than $\pm 0$ m. The probable errors of the apparent magnitudes, $V_{E}$, are near $\pm 0^{\mathrm{m}} 01$ and can be disregarded. The stars in table 1 A are plotted as

TABLE II
Main Sequence Stars With $(\mathbf{P}-V)_{E}$ Between +0 m 45 and +1 m 25

filled circles in figure 3, except for two spectroscopic binaries noted with an asterisk in the table, and plotted as crosses in the figure. The standard main sequence, defined by the stars in the Praesepe and Pleiades clusters, is indicated by two bands: one, $0^{m} .1$ wide in $M_{V}$ for stars redder than +0.28 , and the other, $0^{m} 2$ wide for the bluer stars. The width of these bands represents the dispersion, about an infinitely narrow sequence, of the defining stars.

There are two rather striking features in the distribution of the filled circles in figure 3; (a) the stars redder than $(P-V)_{E} \cong+0$ m. 45 seem to fall into sequences, one the main sequence defined by the Praesepe stars, and the other, below it, and (b) all but two of the bluer stars fall above the main sequence. The 17 main sequence stars redder than $(P-V)_{E}=+0^{\mathrm{m}} 45$, except for the two spectroscopic binaries already mentioned, are listed in table II. The photometric parallaxes, $\pi(p t)$, were computed on the assumption that any displacement of these stars from the main sequence drawn in figure 1 , is due to errors in the parallaxes. The mean percentage error, $\epsilon(\%)$, or $100[\pi(t)-\pi(p t)] / \pi(t)$, is zero, since the value of $K=-6^{\mathrm{m}} 04$, adopted above for the Praesepe cluster, was determined from a direct comparison
of these stars with cluster stars of the same color. The average percentage-error, without regard to sign, is 4.2 per cent, or $\pm 0.0055$ for the average parallax of 0 " 134 . According to the precepts given in the parallax catalogue, the average weight of 50

TABLE III
Subluminous Stars

| Yale | Star |  | $(P-V)_{\boldsymbol{R}}$ | $M_{V}$ | $V_{r}$ |
| :---: | :--- | :---: | :---: | :---: | :---: |
| 4849 | HR 7783 | $+0^{\mathrm{m} .48}$ | $+5^{\mathrm{m} .04}$ | -5 | $V_{\boldsymbol{r}}$ |

| 1314 | HD 38230 | +0.73 | +6.69 | -31 | 45 |
| 2082 | HD 74377 | +0.835 | +7.38 | -26 | 60 |

Color-luminosity array for stars near the sun
for the stars in table II corresponds to a probable error of $\pm 0.0045$ in the parallax.
The six subluminous stars in table III appear to form a separate group falling approximately a magnitude below the main sequence. The radial $V_{r}$ and tangential $V_{T}$ components of the motion with respect to the sun are listed for these stars, as they are for the main sequence objects in table II. The radial velocity of one southern hemisphere star in table III is unknown. Although several of the stars
in table III have rather high velocities, the motion alone does not distinguish them from the stars in table II, since the total range of the velocities is nearly the same in the two tables.

We next consider the stars in sections B and C of table I. These stars are plotted in figure 3 as open circles, except that again the spectroscopic binaries are indicated by crosses. Since parallax weights of 15 and 20 correspond to probable errors of $\pm 0.008$ and $\pm 0$ ". 007 , respectively, in the parallaxes [1], from equation (2) we find that the largest probable errors in the absolute magnitudes will be about $\pm 0 \mathrm{~m} 35$ for stars in both groups.

From the distribution of the points in figure 3, we may draw the following conclusions:
(a) The stars bluer than $(P-V)_{E} \cong+0^{m} 4$ fall mainly above the main sequence. Although the absence of stars redder than $(P-V)_{E} \cong+0^{\mathrm{m}} 5$, between $M_{V}=+3^{\mathrm{m}}$ and $+4^{\mathrm{m}}$, and also the V-shaped "zone of avoidance" with apex near $(P-V)_{E}=$ $+0^{\mathrm{m}} .6$ and $M_{V}=+3^{\mathrm{m}}$, probably represent a real scarcity of stars; the smallness of the samples considered, and the effects of recognized selection factors, make any further conclusions precarious.
(b) The absence of stars in the region below $M_{V}=+4^{\mathrm{m}}$ and above the main sequence is apparently a real phenomenon.
(c) The nearby dwarf stars redder than $(P-V)_{E} \cong+0^{m} .45$, like those in the clusters, define a main sequence that is certainly less than 0 m 2 , and probably less than $0^{m} 1$ wide.
(d) There is a definite subdwarf sequence that lies about one magnitude below the main sequence at $(P-V)_{E}=+0^{\mathrm{m}} 8$ and approaches to within $0^{\mathrm{m}} .5$ of the main sequence at $(P-V)_{E}=+0^{\mathrm{m}} 5$. Although again the sample of stars is small, there is apparently a clear division between the two sequences.
