# A LIMIT THEOREM FOR INDEPENDENT RANDOM VARIABLES 

DONALD ORNSTEIN<br>Stanford University

The starting point of this paper is the question, what happens to the distribution of the sum of a large number of independent, identically distributed, integer valued, random variables or equivalently, what happens to a measure on the group of integers when convoluted by itself a large number of times? It is known that the probability of being at a fixed integer tends to a limit and that this limit is 0 . Therefore, the finer information about what the distribution looks like is obtained by looking at the ratio of the probability of being at one fixed integer to the probability of being at another fixed integer. Such a theorem was proved by Chung and Erdös in [1].

There are two natural directions for generalizing this theorem. One generalizes to a Markov process and the other to convoluting measures on a more general group.

A generalization to Markov chains is given by Kingman and Orey in [3]. Another generalization is given by Jain in [2] for a fairly general Markov process, but the price for the generality is that the theorem is about the ratio of the expected number of visits to a set up to time $n$ instead of the probability of being there at time $n$.

In this paper we generalize to convoluting on more general groups and prove a theorem in the case where the group is the line. The method used is a modification of the one used by Chung and Erdös. This method gives the same theorem for Euclidean space, and if we analyze the proof, we see that we use very little that is specific to the line, and hence we could get a theorem for a general locally compact abelian group. (Our assumption of mean 0 is used only in obtaining lemma 1, and hence in all cases when we have lemma 1 , we have a general theorem.) We could do the same for the time ratio, thus generalizing theorem 4 of [1].

Charles Stone recently gave another proof of the main theorem of this paper in [4]. His method seems to give more information in the case of Euclidean space but does not seem to go over to more general groups.

Theorem. Let $X_{n}$ be a sequence of independent, identically distributed, realvalued random variables with either mean 0 or with the integral of the positive and negative parts both infinite. Assume also that the values $X$ takes are not all part of an arithmetic progression. Let $S_{n}=\sum_{i=1}^{n} X_{i}$. Let $J_{1}$ and $J_{2}$ be two intervals of the same length. Then

$$
\begin{equation*}
\lim _{n \rightarrow \infty} \frac{\operatorname{Pr}\left\{S_{n} \subset J_{1}\right\}}{\operatorname{Pr}\left\{S_{n} \subset J_{2}\right\}}=1 \tag{1}
\end{equation*}
$$

The abbreviation $\operatorname{Pr}$ stands for probability of the event which follows in braces.

Lemma 1. Given $\epsilon$ and an interval $J, \operatorname{Pr}\left\{S_{n} \subset J\right\}>(1-\epsilon)^{n}$ for all sufficiently large $n$.

Proof. The proof is similar to the proof of theorem 2.2 in Erdös and Chung and will therefore be omitted.

Lemma 2. There are arbitrarily small numbers $\alpha$ such that there is an integer $k$ and arbitrarily small pairs of intervals $I$ and $I^{\prime}$ where $\operatorname{Pr}\left\{S_{k} \subset I\right\} \neq 0$ and $\operatorname{Pr}\left\{S_{k} \subset I^{\prime}\right\} \neq 0$ and $I$ and $I^{\prime}$ are $\alpha$ apart in the sense that there is a point in $I$ that is at distance $\alpha$ from some point in $I^{\prime}$.

Proof. This is straightforward and easy and will therefore be omitted.
Definition. Let I be an interval. We shall call the interval obtained by extending $I$ in both directions by $\epsilon, I^{e}$ and the one obtained by contracting by $\epsilon, I^{-\epsilon}$.

Lemma 3. Let $J_{1}$ and $J_{2}$ be disjoint intervals of the same length whose centers are $\alpha$ apart, and lemma 2 applies to $\alpha$. Then given $\epsilon>0$ and $\gamma>0$, there is a $K$ such that

$$
\begin{equation*}
\frac{\operatorname{Pr}\left\{S_{n} \subset J_{2}^{\epsilon}\right\}}{\operatorname{Pr}\left\{S_{n} \subset J_{1}^{-\epsilon}\right\}}>1-\gamma \quad \text { for all } n>K \tag{2}
\end{equation*}
$$

Proof. By lemma 2 there are intervals $I$ and $I^{\prime}$ and an integer $k$ such that there is a point in $I$ and a point in $I^{\prime} \alpha$ apart, the lengths of $I$ and $I^{\prime}$ are both $<\epsilon$, and $\operatorname{Pr}\left\{S_{k} \subset I\right\}=p \neq 0$ and $\operatorname{Pr}\left\{S_{k} \subset I^{\prime}\right\}=p^{\prime} \neq 0$ [to fix ideas, assume $J_{2}$ is to the right of $J_{1}$ and that $I^{\prime}$ is to the right of $I$ and that $\epsilon$ is small compared to $\alpha$ so that $I$ and $I^{\prime}$ are disjoint. Take all intervals from now on to be half open].

To simplify notation, we will prove lemma 3 only for $n$ of the form $m k+r$ ( $0 \leq r<k$ ) $(0 \leq m<\infty)$ for just one $r$ so we can keep $r$ fixed throughout the proof. Call the random variable $S_{r}, \bar{X}_{0}$ and let $\bar{X}_{i}=\sum_{j=r+1+k(i-1)}^{j=r+i k} X_{j}$. Let $T_{I, m}(w)$ be the number of $\bar{X}_{2}(w)$ that are in the interval $I(1 \leq i \leq m)$. It is well known that given $\gamma_{1}$ (choose $\gamma_{1}$ so that $\left(1-\gamma_{1}\right)^{2} /\left(1+2 \gamma_{1}\right)>1-\gamma$, where $\gamma$ is the $\gamma$ in lemma 3), there is a $\delta<1$ such that $\operatorname{Pr}\left\{\left|\left(T_{I, m}\right) /(p m)-1\right|>\gamma_{1}\right\}<\delta^{m}$ for all $m$. Hence, using lemma 1 , we get

$$
\begin{array}{ll}
\operatorname{Pr}\left\{\left|\frac{T_{I, m}}{p m}-1\right|>\gamma_{1}\right\}<\gamma_{1} \operatorname{Pr}\left\{S_{m k+r} \subset J_{1}^{-2 e}\right\} & \text { for all } m \text { large enough, }  \tag{3}\\
\operatorname{Pr}\left\{\left|\frac{T_{I^{\prime}, m}}{p^{\prime} m}-1\right|>\gamma_{1}\right\}<p^{\prime} \gamma_{1} \operatorname{Pr}\left\{S_{m k+r} \subset J_{2}\right\} \quad \text { for all } m \text { large enough. }
\end{array}
$$

Let $m^{\prime}$ be an $m$ for which (3) and (4) work, and let $n^{\prime}=m^{\prime} k+r$. We will prove lemma 3 for $n^{\prime}$.

Break up the real numbers into half open intervals, each of which has length $<\epsilon \cdot 1 / n^{\prime}$ and lies either entirely inside or outside $I$ and $I^{\prime}$, and $I$ and $I^{\prime}$ are broken up into the same number $t$ of intervals. Denote those intervals in $I$ by $g_{1}, \cdots, g_{t}$, those in $I^{\prime}$ by $g_{1}^{\prime}, \cdots, g_{\imath}^{\prime}$, and the rest by $h_{1}, \cdots, h_{\ell}, \cdots$.

For each $w$ we get a sequence $v$ of $m$ intervals, the $i$-th interval being the interval that $\bar{X}_{i-1}(w)$ is in. Let $Q_{v}$ be the set of $w$ with the sequence $v$.

Let $B$ be the union of all those $Q_{v}$ that contain a $w$ for which $S_{n^{\prime}}(w) \subset J_{1}$, and $B^{\prime}$ the union of the $Q_{v}$ that contain a $w$ for which $S_{n^{\prime}}(w) \subset J_{2}^{+2 \epsilon}$.

Define a new measure space $\hat{B}$ as follows: for each $Q_{v}$ in $B$ take as many copies as there are $g$ (that is, subintervals of $I$ ) in the second through last terms of the sequence $v$ (that is, we will take $T_{I, m^{\prime}}(w)$ copies of $Q_{v}$ where $w \subset Q_{v}$ ). Let $Q_{0}^{i}\left(1 \leq i \leq T_{I, m^{\prime}}(w)\right)$ be the copies of $Q_{v}$. Let

$$
\hat{B}=\bigcup_{Q_{0} \subset B}\left(\begin{array}{c}
T_{I, m^{\prime}}(w)  \tag{5}\\
\left(w \subset Q_{0}\right) \\
i=1
\end{array}\right) Q_{0 .}^{i}
$$

The measure of a set in $\hat{B}$ will be the sum of the measure of the set intersected with each of the $Q_{0}^{i}$. Call the measure $\mu(u(\hat{B})$ is much larger than the measure of $B$, for example).

Define $\hat{B}^{\prime}$ in a similar way; namely,

$$
\hat{B}^{\prime}=\bigcup_{Q_{0} \subset B^{\prime}}\left(\begin{array}{c}
i=T_{I^{\prime}, m^{\prime}}(w)  \tag{6}\\
\binom{\left(w \in Q_{0}\right)}{i=1} Q_{0}^{i}, ~
\end{array}\right.
$$

(we will call the measure on $\hat{B}^{\prime} u$ and also the measure on our original probability space $u$ ).

To each $Q_{0}^{t}$ in $\hat{B}$ there corresponds a $Q_{v^{\prime}}$ in $B^{\prime}$ as follows: the index $v^{\prime}$ will be obtained by changing the $i$-th $g$ in the second through last terms of $v$, call it $g_{j}$ into $g_{j}^{\prime}$ and leaving the rest of the sequence alone. It is easy to check that $Q_{v^{\prime}}$ is in $B^{\prime}$.

Each $Q_{v^{\prime}}$ in $B^{\prime}$ has at most $T_{I^{\prime}, m^{\prime}}(w),\left(w \subset Q_{v^{\prime}}\right)$ inverse images (this is easy to check). Hence, we can get a one-to-one mapping $\hat{B}$ into $\hat{B}^{\prime}$ such that if $Q_{0}^{i} \rightarrow Q_{v^{\prime}}^{j}$ then $v^{\prime}$ will be obtained from $v$ by the process described in the previous paragraph.

Partition $\hat{B}$ into disjoint pieces $D_{j}$ in the following way: the set $Q_{v}^{i}$ will be in the same group as $Q_{\bar{b}}^{j}$ if $i=j$ and $v$ and $\bar{v}$ differ in only one coordinate, the $i$-th $g$ of the second through last terms of $v$ (or equivalently $\bar{v}$ ). Call $D_{j}$ full if it contains a $Q_{0}^{i}$ for every possible choice of $g$ for the $i$-th $g$ (that is, if there are $t, Q_{0}^{t}$ in $D_{j}$ ). (The set $D_{j}$ may not be full because some of the necessary $Q_{v}$ may not be in $B$.)

It is easy to see that every $Q_{0}^{t}$ such that there is a $w$ in $Q_{v}$ with $S_{n^{\prime}}(w) \subset J_{1}^{-2 \epsilon}$ is in a full $D_{j}$. Call the union of the $Q_{v}$ that contain a $w$ with $S_{n^{\prime}}(w) \subset J_{1}^{-2 \epsilon}, B_{-2 \epsilon}$.

If $D_{j}$ is full and $D_{j}^{\prime}$ is its image, then

$$
\begin{equation*}
u\left(D_{j}\right)=\frac{\boldsymbol{p}^{\prime}}{\boldsymbol{p}} u\left(D_{j}\right) \tag{7}
\end{equation*}
$$

This comes from the independence of the $\bar{X}_{i}$.
By (3) the measure of the part of $B_{-2 \epsilon}$ for which $T_{I, m^{\prime}}>p m^{\prime}\left(1-\gamma_{1}\right)$ is greater than $\left(1-\gamma_{1}\right) u\left(B_{-2 \epsilon}\right)$. Hence, the measure of the full $D_{j}$ in $\widehat{B}$ is greater than

$$
\begin{equation*}
p m^{\prime}\left(1-\gamma_{1}\right)\left(1-\gamma_{1}\right) u\left(B_{-2 \epsilon}\right) . \tag{8}
\end{equation*}
$$

Combining (7) and (8) we get

$$
\begin{equation*}
u\left(\hat{B}^{\prime}\right)>\frac{p^{\prime}}{p} \cdot p m^{\prime}\left(1-\gamma_{1}\right)\left(1-\gamma_{1}\right) u\left(B_{-2 \epsilon}\right) \tag{9}
\end{equation*}
$$

By (4), the measure of the part of $B^{\prime}$ for which $T_{I^{\prime}, m^{\prime}}>p^{\prime} m^{\prime}\left(1+\gamma_{1}\right)$ is less than $p^{\prime} \gamma_{1} u\left(B^{\prime}\right)$. Hence, $u\left(\hat{B}^{\prime}\right)<u\left(B^{\prime}\right) p^{\prime} m^{\prime}\left(1+\gamma_{1}\right)+m^{\prime} p^{\prime} \gamma_{1} u\left(B^{\prime}\right)$, and

$$
\begin{equation*}
u\left(\hat{B}^{\prime}\right)<u\left(B^{\prime}\right) p^{\prime} m^{\prime}\left(1+2 \gamma_{1}\right) \tag{10}
\end{equation*}
$$

Putting (9) and (10) together we get $u\left(B^{\prime}\right) p^{\prime} m^{\prime}\left(1+2 \gamma_{1}\right)>p^{\prime} m^{\prime}\left(1-\gamma_{1}\right)\left(1-\gamma_{1}\right)$ $\times u\left(B_{-2 \epsilon}\right)$ and

$$
\begin{gather*}
u\left(B^{\prime}\right)>\frac{\left(1-\gamma_{1}\right)^{2}}{\left(1+2 \gamma_{1}\right)} u\left(B_{-2 \epsilon}\right),  \tag{11}\\
\operatorname{Pr}\left\{S_{n^{\prime}} \subset J_{2}^{+3 \epsilon}\right\}>u\left(B^{\prime}\right), \tag{12}
\end{gather*}
$$

and

$$
\begin{equation*}
u\left(B_{-2 \epsilon}\right)>\operatorname{Pr}\left\{S_{n^{\prime}} \subset J_{1}^{-2 \epsilon}\right\}>\operatorname{Pr}\left\{S_{n^{\prime}} \subset J_{1}^{-3 \epsilon}\right\} . \tag{13}
\end{equation*}
$$

Inequality (11) together with (12) and (13) proves the lemma for $3 \epsilon$, and hence for $\epsilon$.

Lemma 4. Let I and $\hat{I}$ be intervals such that the length of $I$ is greater than $k$ times the length of $\hat{I}\left(\right.$ let $\epsilon=\frac{1}{4}$ length of $\left.\hat{I}\right)$. Then $\operatorname{Pr}\left\{S_{n} \subset I^{-\epsilon}\right\}>\frac{1}{6} k \operatorname{Pr}\left\{S_{n} \subset I^{-\epsilon}\right\}$ for all sufficiently large $n$.

Proof. We can fit more than $\frac{1}{3} k$ intervals, $I_{j}$, of length $4 \epsilon$ into $I^{-\epsilon}$ such that $I_{j}^{e}$ is disjoint from $I_{i}^{e}$ if $i \neq j$. Now apply lemma 3 ( $\frac{1}{3} k$ times) with $\gamma<$ $\frac{1}{2} \hat{I}=J_{1}$ and $I_{j}=J_{2}$.

We get our theorem by combining lemmas 3 and 4 .
